Preface

This thesis began life as a study of the interaction between turbulent eddies and normal shock waves. Von Karman Streets behind a cylinder were to be used to provide a regular eddy pattern, and both hot-film anemometer measurements and schlieren photographs were used to gain information on the Karman Street vortices before, during, and after the shock's passage. However, the further along Lieutenant Colonel Jumper, my advisor, and I progressed, the more we realized that we really did not understand what the anemometer data was telling us about the character of the vortices passing by it. Consequently, we delved into the problem of how to characterize each individual vortex based on the data from a single hot-film anemometer and a schlieren photograph of the vortex. The result of that effort is this thesis; unfortunately, due to time constraints, we never did study the shock-wave/vortex interaction.

I would like to thank my advisor, Lieutenant Colonel Eric Jumper, for his support and encouragement through the inevitable highs and lows of a thesis effort, and my committee members, Dr. William Elrod and Dr. James Hitchcock, for their assistance. My appreciation also to

Leroy Cannon, Jay Anderson, and Nick Yardich, of the Department of Aeronautics and Astronautics Laboratory for their help and their patience with an experimental neophyte, and to Carl Shortt and Ron Ruley of the AFIT Shop for the excellent machine fabrication support. Finally, I would like to thank John Anthony, my son, and most importantly of all, Beth, my wife, for their patience over the last few months. They deserve a break from school more than I do.

— John B. Wissler

Abstract

This investigation involved taking schlieren and hot-film anemometer data on Karman vortex streets, then developing a means of characterizing the individual vortices in a street using a schlieren picture and the corresponding anemometer trace. A ThermoSystems, Inc. IFA-100 anemometer system, with a Tektronix 425 oscilloscope was used to record an anemometer trace. The trace was captured on photographic film. The oscilloscope also fired a Cordin Model 5401 Spark Lamp, which provided, via a schlieren optical system, a physical picture of the Karman Streets formed behind a 5/16-inch dia cylinder in a 2-inch by 2-inch square cross-section test region with a Mach 0.43 flow. Distance and angle information were obtained from the schlieren photographs, and timing and anemometer output voltage were obtained from the anemometer trace photograph using an HP-9874A digitizer. The data was analyzed using a Newton-Raphson method to solve for two constants, c_1 and c_2 , which should have completely characterized the vortices in the vortex street, assuming the vortices followed the theoretical equation for a combined free and forced vortex. It was assumed that the superposition of two vortices plus the mean flow were the

parameters influencing the flow at any point in space and time. The core supremacy principle, which says that in a vortex core only one vortex contributes to the flow, was used in the data analysis. It was found that generally close fits between the theoretical data using the solved for constants c_1 and c_2 , and the experimental data from the anemometer were possible, thus indicating reasonable vortex characterization.

A SCHLIEREN AND HOT-WIRE INVESTIGATION
OF KARMAN VORTEX STREETS

I. Introduction

An object immersed in a flow of fluid, under certain conditions, will give rise to a phenomenon known as the Karman vortex street, an alternating series of eddies or vortices being periodically shed from the downstream side of the object (Figure 1). This phenomenon occurs in compressible or incompressible flow, and has been extensively investigated over the years both experimentally and theoretically (1; 2; 3; 4).

Because the Karman street is such a regular, and hence readily characterized pattern of vortices, one could conceivably use a Karman street to investigate turbulence. Weston attempted to use the vortices to investigate turbulence effects on laser beam propagation (5). However, difficulties in getting a reliable Karman street led to a further study by Clark on how to consistently generate a vortex street (6). By subjecting a vortex street to shocks of varying strengths, one could conceivably gain information on turbulent energy transfer and eddy effects.

With these thoughts in mind, the following objectives were devised as the focus of this research:

Fig. 1. Karman Street Vortex Behind a
Wedge from Clark (6:5)

1. Design and construct a facility capable of generating a Karman vortex street and subjecting the street to a normal shock wave.

2. Starting with the successful results of Clark (5), develop a means of characterizing the vortices in the Karman vortex street using both schlieren photography and hot-wire anemometry.

The rest of this research report focuses on the approach taken and the results of the investigation. Section II discusses the theory and approach. Section III describes the experimental apparatus and Section IV details the experimental procedure. Section V discusses the results of the research and Section VI lists the conclusions drawn. Finally, Section VII contains a list of recommendations for further work.

II. Theory and Approach

As mentioned before, vortices have been investigated extensively, including their interaction with shock waves. Some definitions and derivations will be recalled for background, then some ideas with respect to experimental analysis of Karman Streets will be developed.

Vortices and Their Formation

Broadly defined, a vortex is a "finite volume of rotational fluid, bounded by irrotational fluid or solid walls" (9:1). Schlichting shows a theoretical vortex as having an approximately linear velocity profile for a certain distance out from its center (the rotational core), surrounded by a transition region and a velocity profile varying inversely with r (4:89). The theoretical profile for an incompressible vortex, shown in Figure 2, is well supported by experimental results, an example of which is shown in Figure 3, which is based on dynamic-stall-induced vortices over airfoils (7:119). The radial decay outside the core is due to viscous effects, which also cause the vortex to flatten out and dissipate with time. The vortex of Figure 2 is described by the equation (4:89)

$$u(r,t) = \frac{\Gamma_0}{2\pi r} (1 - \exp(-r^2/4\nu t)) \quad (1)$$

Fig. 2. Theoretical Profile for an Incompressible Vortex

Fig. 3. Dynamic-Stall-Induced Vortex

where

u = tangential velocity

Γ_0 = circulation of vortex at time = 0

ν = dynamic viscosity

\bar{t} = time from formation as an ideal $(1/r)$ vortex

Note that as r increases, $u(r,t)$ approaches a theoretical, irrotational free vortex ($u = \Gamma_0/2r$).

Because the hot wire or hot-film anemometer is sensitive to the product of density, ρ , and velocity, u , of the fluid flowing across the wire/film (13:13), the density distribution of a vortex is also important. Starting with the incompressible equation (1) together with the radial momentum Navier-Stokes equation simplified for compressible, tangential flow (i.e. closed circular streamlines),

$$\frac{u^2}{r} = \frac{1}{\rho} \frac{\partial P}{\partial r} \quad (2)$$

one can arrive at equation (3), which gives a relationship for density variation across the vortex (8:222):

$$\frac{\rho_0 - \rho}{\rho} = \left(1 - \frac{K}{t}\right)^{\frac{1}{k-1}} - 1 \quad (3)$$

where

ρ_0 = density at vortex center

k = polytropic exponent (1.4 for air)

\bar{t} = time from formation as an ideal vortex

$$K = ((k-1)/k\gamma) (\Gamma_{OT}/4\pi)^2 * \rho / P * L(\eta_a)$$

$$L(\eta_a) = \lim \int_0^{\eta_a} \frac{1}{\eta^3} [1 - \exp(-1.259\eta^2)]^2 d\eta$$

r_0 = core radius

$$\eta = r/r_0$$

η_a = outer (ambient) limit of vortex

Equation (3) assumes an isentropic relationship between pressure and density.

Fig. 4. Density Distribution Across a Vortex

As shown in Figure 4, the density is less in the center of the vortex, and greater on the extremities (8:221). This is due to centripetal (body) forces tending to move fluid away from the center of the vortex. This distribution form has been confirmed in other experimental and

computational studies (10; 11). Note also that the differences in densities across the vortex disappear with time, for the same reasons the rotational velocity disappears. Because the density changes are low (within 5 percent), the normal assumption is an approximately constant density across the vortex street for the purpose of mass-flow calculations.

Vortices can be formed by fluid flowing around an immersed object. Considering flow around a cylinder, as the fluid traverses the cylinder's surface it forms a boundary layer, and the pressure distribution first falls then rises (4:29). Eventually, the boundary layer separates away from the cylinder surface, and the fluid downstream of the separation point is entrained in a region of backflow, or recirculating fluid. As the velocity increases, a "bound" vortex first forms, then, with still higher velocities, breaks away, first on one side of the cylinder, then on the other, in a regular, periodic manner (3:18). Thus, the von Karman Vortex Street is formed.

The vortices are shed from a given side at a frequency which can be related to the Reynolds Number based on cylinder diameter. This relationship is given by Strouhal Number, S ,

$$S = fD/V \quad (4)$$

where

f = shedding frequency from one side

D = cylinder diameter

V = freestream velocity

as a function of Reynolds Number, Re_D

$$Re_D = VD/\nu \quad (5)$$

where ν = kinematic viscosity. This relationship between these parameters has been determined empirically and is shown in Figure 5 (4:32).

Fig. 5. Strouhal Number versus Reynolds Number for Flow over a Cylinder

Roshko (3) has identified four flow regimes in the S versus Re_D curve. When the Re_D is less than 40, one has symmetric, viscous flow behind the cylinder, where the vortices are bound. Between Re_D values of 40 and 150, the vortices begin to shed in a stable manner, forming a

stable vortex street (3:816). The vortex flow is predominantly laminar. Between Re_D values of 150 and 300, the shedding and vortices are in transition, starting as laminar flow immediately behind the cylinder (Figure 6). The vortices passing into the vortex street are purely turbulent (3:817).

Fig. 6. Vortex Shedding

Beyond Re_D of 300, transition has occurred, and the shedding is irregular and highly turbulent. Once the Re_D reaches approximately 100,000, the transition occurs in the cylinder boundary layer ahead of the separation point (3:817) and the Karman streets no longer form.

Generation of a Vortex

To shorten the research task, Clark's successful results with an enclosed jet over a cylinder were used (6). Although the Re_D would suggest uncertain results in the street pattern, Clark's experiments show regular streets

to be present. Further, the flow is sufficiently compressible so that schlieren techniques could be used.

Flow Visualization

The well-known technique of Toeppler-schlieren photography was used to visualize the flow. The technique uses changes in the fluid's index of refraction caused by changes in fluid density in order to bend a collimated beam of light, thus varying the light intensity falling on photographic film (5; 6).

The photographs were correlated via timing information with hot-wire or hot-film anemometer data, so that one could associate a mass flow per area or velocity with a specific location in the vortex. Using this visual and flow information, it is theoretically possible to characterize the observed vortices.

Flow Measurement

As mentioned earlier, flow-rate information was obtained using a hot-wire or hot-film anemometer. The anemometer is simply a heated wire placed in a flowing fluid, with the convection heat transfer rate from the wire determined principally by the mass flow of the fluid perpendicular to the wire axis (12:109; 13:13).

Considering an ideal vortex street "rolling" past a wire, anemometer output consists of a steady-state value, which is a time average of the flow past the wire, as well

as a fluctuating component superimposed over the steady-state value. In the case of a series of vortices of equal strength but alternating rotation passing by the anemometer, the variation should be periodic though not necessarily sinusoidal. If one uses autocorrelation and spectrum analysis techniques on the wire output (6:10-14), one can get a good indication of the periodicity of the vortex street. This technique is also useful in verifying the street's existence. If the wake of the cylinder has no order whatsoever, the autocorrelation and spectrum analysis would reveal no regularity or predominant frequency (the shedding frequency).

Data Analysis

There are two major aspects to the data analysis task: location of the data point in the vortex and interpretation of anemometer output.

If one considers a schlieren photograph of a vortex (Figure 7), it is possible to pick out a region that appears to be a core, the semi-circular, darker area being half of the core, surrounded by a swirling outer region. For the purpose of this study the center of the vortex is taken to be the center of the major diameter of the darker area. The location of the anemometer with respect to the vortex is determined by measuring from the vortex center using the 1-inch scale in the picture.

1. Half moon
2. Flow direction
3. Center

Fig. 7. Schlieren Photograph of a Vortex Street

It is possible to gain an insight into the flow past the anemometer by conducting a thought experiment on graph paper. One begins the experiment by constructing a hypothetical Karman street, as shown in Figure 8. Each vortex is assumed to have a tangential mass-flow per unit area profile similar to Figure 2, to translate with a mass-flow vector as shown in Figure 8, and to decay to zero within a distance slightly greater than the vortex spacing. By using a vector sum of the translational and the tangential flow vectors of the three nearest vortices, one can "build" an anemometer signal similar to actual signals

Fig. 8. Imaginary Karman Street

(Figure 9). This signal can then be used as "experimental data" for later thought experiments.

Because the only information available from the anemometer is magnitude and not direction, some assumptions and mathematical manipulations are necessary in order to arrive at meaningful results. Let us first examine the case of a single vortex convecting in a uniform stream. We first assume that the average flow is parallel to the test section walls. We also assume that there is no spiralling or transverse (along the long axis of the vortex) motion associated with the fluid in the vortex. In other words, any flow vector experienced by the anemometer consists only of an average flow vector plus a pure tangential flow vector.

Using the schlieren photograph, we can determine the angle θ and the distance r of the anemometer from the vortex center (Figure 10). Defining $(\bar{\rho V})$ as the convective mass flow per unit area and (ρV) as the mass flow per unit area at the instant the photograph was taken, through geometry it is possible to find (ρu) , the tangential mass flow per unit area.

From Figure 10, one can derive a second angle γ such that

$$(\rho u) * \sin\theta = (\rho V) * \cos\theta - (\bar{\rho V}) \quad (6)$$

Fig. 9. Anemometer Traces from Imaginary Street (i.e., "experimental data")

Fig. 10. Definition of Angles for Single-Vortex Assumption

and

$$\sin\gamma = (\rho u) * \cos\theta / (\rho V)$$

Recalling that

$$\cos\gamma = (1 - \sin^2\gamma)^{\frac{1}{2}} = (1 - ((\rho u) * \cos\theta / (\rho V))^2)^{\frac{1}{2}} \quad (7)$$

we can see, after substituting Equation (7) into Equation (6) and simplifying, that

$$V1 = V2 * \sin\theta + (1 - V2^2 * \cos^2\theta)^{\frac{1}{2}} \quad (8)$$

where

$$V1 = (\rho u) / (\rho V)$$

$$V2 = (\overline{\rho V}) / (\rho V)$$

Thus, it is possible to find the tangential mass flow per unit area.

Examining the single-vortex assumption, where the signal is assumed to be influenced only by the nearest vortex and the translational flow, one can graphically conduct the mathematical analysis developed in Equations (6), (7), and (8), and generate an "experimental" profile for a vortex in the street. If the single vortex assumption is correct, the processed experimental data should exactly yield the vortex profile used to originally build the street. Instead, the result exhibits much scatter (Figure 11) about the exact profile. Consequently, despite

Fig. 11. Profile Using Single Vortex Analysis

its simplicity, the single vortex assumption is inadequate for acceptable analysis.

The case for two vortices of equal but opposite strength is considerably more complex algebraically, and is fully developed in Appendix A. The analysis is based on the assumption that each vortex is of the form

$$(\rho u) = (c_1/r) (1 - \exp(-c_2 r^2)) \quad (9)$$

after Equation (1). Because the density variations across the vortex are not great (8:222), we assume that the mass flow per unit area profile of the vortex is not greatly different from its velocity profile. Performing another thought experiment using hypothetical velocity and density profiles, one can see that the general form should not change (Figure 12).

The tangential flow (ρu) of each vortex can be resolved into horizontal (x) and vertical (y) components. The translational velocity times average density constitutes a horizontal mean flow vector. Via the general vector relation:

$$\begin{aligned} (\text{resultant magnitude}) = & ((\sum \text{horizontal components})^2 \\ & + (\sum \text{vertical components})^2)^{1/2} \end{aligned}$$

one arrives at the two vortex equation:

Fig. 12. Hypothetical Density and Velocity Profiles

$$\begin{aligned}
(\rho V) = & \left\{ \left[\frac{D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \sin \theta_1 \right. \right. \\
& + D_2 \frac{c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \sin \theta_2 \\
& + (\overline{\rho V})^2 + \left[D_1 \frac{c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \cos \theta_1 \right. \\
& \left. \left. + \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \cos \theta_2 \right]^2 \right\}^{\frac{1}{2}} \quad (10)
\end{aligned}$$

where r_1 , θ_1 , and D_1 refer to one vortex and r_2 , θ_2 , and D_2 refer to the other vortex. D_1 and D_2 are the directions of rotation for each vortex, being +1 for counter-clockwise and -1 for clockwise (directions of positive and negative θ , respectively).

Using the "experimental data" from the hypothetical street, one can, once again, graphically construct an "experimental" vortex profile. The contribution of each vortex is unknown before-hand; therefore, one has to use an iterative type approach as shown in Figure 13 to collapse the data from the two-vortex assumption to very close to the original profile used to generate the street. Thus, the two-vortex assumption appears to be valid in analyzing the anemometer data, assuming that the effective vortex radius is on the order of the spacing between consecutive vortices.

There still remains the question of how one solves for the constants c_1 and c_2 in Equation (10), which, as

Fig. 13. Vortex Profile Using Two-Vortex Assumption (solid line is original vortex profile)

written, represents one equation and two unknowns at a particular instant in time and $(r_1, \theta_1, r_2, \theta_2, (\rho V))$. However, if one considers the anemometer output, one has a complete time history of the flow both before and after the schlieren picture was made, as the vortex pair moves in space. By mathematically translating the vortex pair incrementally in time at the translational velocity, one can compute a new set of $(r_1, \theta_1, r_2, \theta_2, (\rho V))$ at each time increment. Note that (ρV) is available from the anemometer trace via the anemometer calibration. Thus, one can obtain multiple sets of data from one anemometer trace and one schlieren picture. The development of these new sets of data is based on simple geometry and is treated in Appendix A.

In theory, since we have two unknowns c_1 and c_2 , we can apply Equation (14) to two sets of data to obtain the two equations needed to solve for the two unknowns. However, Equation (10) is highly nonlinear, making an explicit solution impossible. Furthermore, there are noise and experimental error associated with each set of data, so that even if an explicit solution were possible algebraically, an exact solution would be impossible due to the errors.

Because of the experimental error and nonlinearity, a nonlinear optimizational-type approach is needed. Using

Equation (10), and following stochastic process theory given by Bronson (16), one can define a function f as:

$$f_i(c_1, c_2) = f_{i1}(c_1, c_2) + f_{i2}(c_1, c_2) + f_{i3}(c_1, c_2) + f_{i4}(c_1, c_2) \quad (11)$$

where

$$f_{i1} = c_1^2 / r_1^2 (1 - \exp(-c_2 r_1^2))^2$$

$$f_{i2} = 2(\sin\theta_1 \sin\theta_2 + \cos\theta_1 \cos\theta_2) c_1^2 (1 - \exp(-c_2 r_1^2)) \cdot (1 - \exp(-c_2 r_2^2))$$

$$f_{i3} = c_1^2 / r_2^2 (1 - \exp(-c_2 r_2^2))^2$$

$$f_{i4} = 2(\rho V) c_1 (D_1 \sin\theta_1 / r_1 (1 - \exp(-c_2 r_1^2)) + D_2 \sin\theta_2 / r_2 (1 - \exp(-c_2 r_2^2))) + (\overline{\rho V})^2 - (\rho V)^2$$

i = data point corresponding to a given time

Defining

$$B_i = [f_i + (\rho V)_i^2]^{\frac{1}{2}} = B_i(c_1, c_2)$$

we can say that the error between theory and experiment is $B_i - (\rho V)_i$. Therefore, squaring the errors and incorporating them into a function z , we arrive at:

$$z = - \sum_{i=1}^N [B(i) - (\rho V)_i]^2$$

where N is the number of data points. By finding the (c_1, c_2) pair which maximizes z, we minimize the error between theoretical and experimental data. The Newton-Raphson technique was adapted to this problem and is developed in Appendix A (16:112).

III. Experimental Apparatus

The experimental apparatus consisted of the flow device and test section, optical equipment, and the hot-wire anemometer. A list of instrumentation is contained in Appendix C.

Flow Device and Test Section

Air for the test was provided by a compressor capable of supplying approximately 0.5 lbm/sec at a nominal pressure of 85 psig. Because the test required approximately 1.5 lbm/sec, it was necessary to operate in a blow-down type of arrangement by drawing down the compressor's accumulator tank. This allowed a maximum run-time of approximately 1 minute.

After entering the laboratory bay, the air proceeded through a cyclone separator and filter, which removed dirt and water. From the separator and filter, the air flowed through 2-inch pipe to a 2-inch gate valve, which served as a master on/off control. It then passed through a Grove Company Model 83 Flex-Flo flow regulator before finally entering a stilling chamber (Figure 14).

The stilling chamber was the same as the one used in Weston's and Clark's research (5; 6). It served to stagnate the incoming flow and also contained honey-comb

grids to smooth out any turbulence at that point. It in turn fed air into the test section via a convergent nozzle.

The test section was designed to duplicate Clark's successful design. To this end, it had a 2-inch by 2-inch square cross-section (total area of 4 square inches) with a 5/16-inch diameter circular bar mounted horizontally through its centerline (Figure 15 and 16). Penetrating the top of the section were two pressure taps and four anemometer taps. The top and bottom of the section were wood and the sides were plexiglass and optical glass. The cylinder was mounted in the plexiglass. The entire section was 4-feet long and was constructed from an existing square shock tube.

At the downstream end of the test section was the outlet assembly, constructed by the AFIT Model Fabrication Shop. It consisted of four square exit ports, each of approximately 1 square inch area, which provide an exhaust area of slightly over 4 square inches for the steady flow (Figure 17). A pneumatic annular slider was designed to close the exit ports when the shock wave was released. Closing off the ports ensures that the shock does not dissipate into the room instead of traveling upstream into the Karman street generated by the steady flow across the cylinder. The slider was configured to be initiated by bottled air through a solenoid valve.

| 3. Annular Slider | |

Fig. 17. Outlet Assembly

The shock tube was attached to the outlet assembly. The shock tube driver was the same as that described by McQueen (13:6-10). The most notable aspect of the tube was the fact that it used the double diaphragm system of operation as opposed to a single diaphragm punctured by a needle. Each diaphragm was capable of withstanding approximately one-half of the needed pressure drop, and the pressure across the diaphragm assembly was increased in stages from low, to an intermediate level between the diaphragms, to high. When the intermediate region was vented to ambient pressure, the intermediate/high pressure diaphragm suddenly experienced a pressure nearly twice its breaking pressure, and so it burst. The low/intermediate diaphragm then found itself in the same predicament and also broke, and the resulting shock wave traveled down the tube toward the test section.

Optical System

The schlieren system originally used a Cooke Model 596-4116 spark lamp aimed through three mirrors and a knife edge to expose Polaroid Type 47 film (ASA 3000) to get a visual picture of the flow conditions behind the cylinder. The spark lamp consisted of a bank of capacitors discharging across a small gap to generate a point source of light of very short duration. A Cordin Model 5205 Power Supply (Figure 18) provided approximately 8000 Volts

Fig. 18. Arrangement of Test Instrumentation

for charging the capacitors. A 200 Volt pulse triggered the spark lamp to discharge. The light traveled to a 40-inch focal length mirror, across the test section in parallel beams to a second 40-inch mirror, and to the knife edge via a plane mirror which turned the light towards the camera. After passing the knife edge, the light exposed the film. Midway through the research, a Cordin Model 5401 spark lamp became available, and it replaced the Cooke spark lamp (Figure 14).

Since it was desirable to correlate the picture with the anemometer data, the spark lamp was triggered after the anemometer oscilloscope began its trace. A 5-Volt signal came out of the delayed gate on the back of the oscilloscope, and passed to a transformer box which produced the 200-Volt signal necessary to trigger the spark lamp. The time delay was measured using a CMC Model 726C Universal Counter turned on at the start of the anemometer trace and turned off when the 200-Volt signal was triggered. Thus, it was possible to determine the point on the anemometer data corresponding to the time the schlieren picture was taken. Two 1-inch lengths of tape on the test section window served as the horizontal and vertical scales for the location of the anemometer as well as the size of the vortices. An HP-9874A digitizer/HP-85 computer system was used to read the schlieren picture for distance information.

Anemometer System

Mass flow per unit area was measured by the Thermo-Systems, Inc. (TSI) IFA-100 Intelligent Flow Analyzer, which consisted of a TSI Model 1214-10 hot film anemometer and the accompanying electronics necessary to receive and process the anemometer signal (Figure 18). To increase resolution on the oscilloscope, the IFA-100 was set for a 2-Volt offset, wherein 2 Volts was subtracted from the bridge output, and oscilloscope sensitivity was increased. Therefore, to get the actual anemometer signal magnitude, one would add 2 Volts to the magnitude of the oscilloscope signal.

A Tektronix AN/USM-425 (Tektronix Model 465M) oscilloscope with a Tektronix C30 Series oscilloscope camera was used to make a permanent record of the anemometer data. The primary reason for choosing the 425 was because it could provide the delayed 5-Volt pulse to trigger the spark lamp. Because it did not have a trace storage capability, it was necessary to photograph the oscilloscope trace as it occurred by leaving the C30 camera shutter open during the event. Exposures were also made of the zero voltage level and the grid. The oscilloscope was triggered by hand when the pressure in the stilling chamber was at the desired value for that particular test run. Unfortunately, this meant that there was no control over the vortices' position relative to the wire. The anemometer data was digitized

Using the HP-9874A digitizer/HP-85 computer system.

Figure 19 shows a schematic of the test instrumentation.

To verify the street's existence, in addition to using the schlieren photography, in initial investigations the anemometer output was fed to an HP-3721A Correlator and an HP-3582A Spectrum Analyzer. A Fluke Model 2100A Digital Thermometer was used to indicate temperature and a Wallace and Tiernan Model FA145 30-in Hg Bourdon Tube gauge was used to measure pressure inside the stilling chamber.

Fig. 19. Schematic of Test Instrumentation (Top View)

IV. Experimental Procedure

Anemometer Calibration

The anemometers were calibrated in a calibrator modeled after the TSI Model 1125 (13:17). By placing them in the exit of a nozzle fed by a stagnation chamber and varying the total-pressure and back-pressure, it was possible to closely simulate the actual experimental conditions. The anemometer output voltage, total-pressure, total-temperature, and back pressure were recorded. At least 10 calibration points were taken.

Isentropic flow equations were used to calculate the mass flow per unit area across the anemometer at each data point. The resulting mass-flow per unit area and voltage were then applied to a BASIC computer program (15:179-182) which solved for the constants m_0 through m_4 in the fourth order polynomial:

$$\rho V(E) = m_0 + m_1 E + m_2 E^2 + m_3 E^3 + m_4 E^4$$

where E is the anemometer output voltage in volts and ρV is the mass-flow per unit area in $\text{lbm/ft}^2\text{-sec}$. Because the total temperature never varied more than a few degrees, temperature differences were considered to have negligible effect.

Vortex Characterization

The general procedure for characterizing the vortices was to obtain the anemometer and schlieren data, mathematically translate it in time to obtain 20 data points, and use the Two-Vortex Assumption to approximate the constants c_1 and c_2 . Errors were checked by comparing the theoretical flows with the experimental flows.

Before each experimental session, the test equipment connections were verified as shown in Figure 19 and the equipment turned on. After a suitable warm-up time, the anemometer frequency response was set using the square wave test function on the IFA-100 (13:23-24).

Once the instrumentation was ready, the room lights were turned off in order to avoid overexposing the schlieren film. The oscilloscope was set for a 5-V delay signal out (B gate on the AN/USM-425) approximately 1 msec after initial triggering. The schlieren and oscilloscope camera shutters were opened, the spark lamp armed, and the delay timer was reset. The experiment was now ready to begin.

Air flow was initiated and controlled by manually opening and adjusting the hand valve so as to maintain 20 in Hg -gauge pressure inside the stilling chamber. After several seconds the hand trigger was pressed, thus triggering the oscilloscope and, after the delay, the spark lamp. The total temperature was also noted.

After data collection, the valve was shut and the camera shutters were closed. The zero level trace and graticule on the oscilloscope were photographed and the pictures were developed.

The photographs were then processed using the HP9874A digitizer. Angle, radius, and average spacing between consecutive vortices were obtained using the schlieren picture and average time interval and voltage history were obtained using the anemometer picture. The information was then applied to the two vortex model and c_1 and c_2 were solved for iteratively. Once c_1 and c_2 were known, they were used to construct a theoretical Karman street for comparison with the experimental street over several periods.

V. Results and Discussion of Results

Initially, it was important to confirm that Karman vortex streets were being produced in the test section. Once it was found that the streets did exist, and operating conditions (stilling chamber pressure) had been selected, the streets could be investigated in detail. The raw experimental data in the form of photographs as well as a summary are located in Appendix D.

Preliminaries

Using autocorrelation and raw anemometer data, one could see that Karman vortex streets existed for stilling chamber pressure (P_{SC}) ranges of 8 to 25 in Hg-gauge. The results were similar to those obtained by Clark (6:69-74). However, at the lower pressures, the Mach numbers were too low for the vortex streets to be visible using schlieren techniques. Although the higher pressures resulted in greater turbulence, optical considerations drove P_{SC} to be from 15 to 25 in Hg-gauge. The stilling chamber pressure of 20 in Hg-gauge was selected as the operating condition. The corresponding test section static pressure (P_{TS}) at the $P_{SC} = 20$ in Hg was 14 in Hg-gauge, which, according to isentropic flow tables, gives a Mach 0.43 flow ahead of the 5/16-inch dia cylinder.

The selection of the P_{SC} of 20 in Hg-gauge created a dilemma from an experimental point of view. In order to get good quality schlieren pictures, there had to be some compressibility effects. This meant the Mach number had to be relatively high, which in turn mandated use of a higher P_{SC} . Unfortunately, a higher Mach number also meant a higher Reynolds number, which meant more chaotic flow behind the cylinder. The Reynolds number based on cylinder diameter was calculated at approximately 100,000, which, according to Figure 4 and Roshko (3), is a region where the Karman street is unstable and irregular. Consequently, there were great variations in the quality of the street, as seen on schlieren photographs and measured by the anemometer. Frequently, only a dead wake was observed. Since the characterization technique required clearly defined vortices, much of the data collected was unuseable.

Initial Investigation

Early test runs were made without the anemometer passing through the core region of the vortices. Consequently, the data collected contained no information about the core. Without information on the core one cannot, with any degree of reliability, expect to completely characterize the vortex. It was decided to place the anemometer wire even with the top edge of the cylinder, so that the vortex centers would pass close by the wire, thus enabling

information to be acquired about the core. The 20 data points used to calculate c_1 and c_2 were evenly distributed along the portion of the trace generated by the two vortices captured on the schlieren picture.

A problem which developed with the Cordin spark lamp was that every time it sparked, a spike of several tenths of a Volt was exhibited on the anemometer trace. This spike defied all attempts to get rid of it, including shielding, grounding, and filtering. Therefore, the 20 data points used in the solution to c_1 and c_2 began at the spark-lamp firing and went backward on the trace (see Appendix D). Additional points running further back were read so as to enable a comparison between the experimental trace and the theoretical trace to be made over several cycles.

A second modification to the analysis method which was made early in the research was to invoke a core supremacy principle. If one considers the vortex core as a rigid rotator, where the fluid is irrotational and spins as a more or less "monolithic" mass of fluid, superposition should not hold within the core region. The only vortex contributing to the flow inside the core should be the nearest one, or the one of which the core in question is a part. An analogy would be a string of solid cylinders spinning and convecting at the same time in a fluid. The region in between the cylinders is influenced by the nearest

spinning cylinders, but the region inside a solid cylinder is obviously influenced only by the cylinder itself.

The analysis program was modified by having it branch to a one-vortex solution whenever the smallest of the two radii was less than a set core radius. The radius chosen for this study was one-half the cylinder diameter, or 5/32-inch, which was approximately the average radius of the cores as observed on the schlieren pictures.

When some of the experimental data was applied to the analysis program, the resulting theoretical Karman street profile for the solved for c_1 and c_2 was almost constant (Figures 20 to 24) instead of the periodic profile exhibited by the corresponding experimental data. Independent of starting values for c_1 and c_2 , the Newton-Raphson method generally converged on low values of c_1 and c_2 as approximations to the actual flow. The Run 092609 (Figure 23) did exhibit some theoretical street formation; the other runs showed simply a flat profile.

If one considers the magnitude of the theoretical street, one finds that it is approximately equal to the product of the convective velocity (V_1 in the program "DATANAL8") and the free stream density (calculated as the test section static pressure divided by the product of the gas constant, R , and temperature, T), or approximately $44 \text{ lbm/ft}^2\text{-sec}$. It is possible that the free-stream density is not an accurate representation of the average

Fig. 20. Run 092502--Theoretical and Experimental Karman Streets

Fig. 24. Run 092611--Theoretical and Experimental Karman Streets

density of the two vortex system used to find c_1 and c_2 . Use of the free-stream density appears to overwhelm any attempts by the analysis program to solve for the vortices, as represented by c_1 and c_2 , that are known to be in existence in the flow. The smallest error between theory and experiment is when no vortices exist; consequently, the analysis drives the c_1 , c_2 solution towards small values, and the profile is flat.

These results could indicate that the density, instead of varying by several percent across a vortex, might in fact vary by up to tens of percent. From a mathematical perspective, a lower average density would give the analysis program an opportunity to come to a solution with nonzero vortices.

Final Investigations

To see whether the average density was in fact lower than the free stream density, the analysis program was modified so as to allow an artificial reduction of the free-stream density to some value determined by a density factor, fd , which was set between zero and one. The density factor entered into the computational scheme only in the calculation of the convective mass flow per unit area (lines 7070, 7480, 7910, 8260, 8290, 8320, 8390, and 8430 in the program "DATANAL8"--see Appendix A). With a lower average density, the rest of the solution adjusted

itself accordingly, and it was possible for nonzero vortex solutions to make more of a contribution to the theoretical flow, thus permitting the periodicity exhibited by the experimental flow.

As shown in Figures 25 to 36, with the proper density factor, one can match the experimental data relatively closely over several cycles. The period also matches, except for a slight phase shift. The phase shift is considered unimportant, because it does not change the essential character and profile of the vortex street.

Increasing the density factor has a dual effect on the theoretical Vortex Street. At low density factors, even large values of c_1 , corresponding to stronger vortices, cannot provide enough mean flow to match the mean flow of the experimental data. Consequently, the whole theoretical curve, even though it matches the general profile of the experimental curve, appears to be offset below the experimental curve. The theoretical curve also has much larger amplitude fluctuations than the experimental curve (Figures 25, 26, 27, 31, and 37, in particular). As the density factor increases, the mean of the theoretical curve rises toward the mean of the experimental curve. However, the theoretical vortices get weaker, as manifested by the smaller amplitude fluctuations (Figures 29 and 30). By the time the factor equals one, where the average density

Fig. 35. Run 202609--Theoretical and Experimental Karman Streets

Fig. 36. Run 092611--Theoretical and Experimental Karman Streets

is equal to the free-stream density, the theoretical curve is almost completely flat (Figures 31 and 32).

Over the 20 points used to calculate c_1 and c_2 , the analysis yields very good agreement with the experimental data. The theoretical Karman street is very periodic, but as time values decrease, agreement with experimental data gets worse. Because the experimental Karman streets are turbulent and irregularly formed, one would expect agreement to get worse. However, the theory does appear to be capturing the essential characteristics of the flow (Figures 28, 33, 34, and 35). Note that the irregularities exhibited by the theoretical flow curves are due to the resolution of the display program.

There was another aspect to the density factor which was considered. Because the factor entered into the computational scheme as:

$$\dots fd * \rho * \bar{V} \dots$$

it could also be considered as modifying the value of \bar{V} and leaving ρ constant.

Prandtl and Tietjens (17:132-133) indicate that the velocity field of a Karman street is due to the superposition of the vortices on the free-stream flow, and not on the translational flow of the vortex centers. It is this difference in velocity that appears to cause the vortices in the street to move towards the (5/16-inch)

cylinder from the point of view of a reference frame attached to the free-stream flow. Thus, the magnitude of the inertial translational velocity of the vortex centers is less than the free-stream velocity. By using fd 's greater than 1.0, one can artificially raise \bar{V} to a value approximately equal to the free-stream velocity. Accordingly, values of fd equal to 1.2, 1.4, and the ratio of free-stream velocity (V_∞) to the measured value of \bar{V} were applied to "DATANAL8." The resulting plots are shown in Figures 37 to 48.

As can be seen, some of the best approximations occurred for the values of fd equal to V_∞/\bar{V} (Figures 40 and 48). Contrary to previous experience, the theoretical curves did not always flatten with increasing density factor, although the theoretical curve for Run 092504 (Figures 21, 38, and 39) was flat for all values of fd greater than or equal to 1.0. There appears to be an optimum value of fd which yields the best approximation to the data; unfortunately, the limitations of the program "DATANAL8" prevent more than a crude estimation of that optimum value. As shown in Figures 40 and 48, the optimum could be the one such that:

$$fd \cdot \rho \cdot \bar{V} = \rho \cdot V_\infty$$

where V_∞ is the free-stream velocity. However, there are also indications that a different value of fd is more

Fig. 48. Run 092611--Theoretical and
 Experimental Karman Streets
 (Prandtl-Tietjens Theory Used)

desirable (Figures 44, 46, and 47). It is probable that a combination of density gradients as well as the V_∞ -vortex superposition apply to the Karman vortex street phenomena and its analysis, especially since the free-stream Mach number is of the order of 0.43.

The criteria for physically realistic values of c_1 and c_2 were simply that they be non-negative and that they be such that a ρu profile of the vortex exhibited a peak at a radius of 0.15 to 0.20 inches, which was the range of core radius observed in the schlieren pictures. Figure 49 shows some sample profiles for various acceptable values of c_1 and c_2 . As with all optimization techniques, frequently the answers providing the best approximation to the experimental data did not satisfy the above criteria for physically correct answers. If c_1 becomes negative, that implies that the vortices are in effect spinning backwards (Figure 50) which is a physical impossibility with Karman vortex streets. If c_2 becomes negative, then, as r increases, (ρu) increases without bound in a negative direction, also an impossibility.

VI. Conclusions

The following conclusions may be drawn from the previously discussed research effort:

1. It is possible, using the ideal, theoretical vortex equation and the ideas of superposition and core supremacy, to characterize the vortices in a Karman vortex street given anemometer and schlieren data. Considering the fact that the experimental flow is highly chaotic and the vortex shedding unstable, one can generate an experimentally based theoretical vortex street which bears reasonably close resemblance to the actual street.

2. The assumption that density is constant across the vortices is not valid in all cases. For true generality, it is necessary to take compressibility and density gradients into account in the analysis. If the flow is actually incompressible, then the analysis must be able to collapse to an incompressible solution.

3. The theoretical analysis by Prandtl and Tietjens, showing that the superposition phenomenon is between the free-stream and the vortex field has merit in efforts to experimentally characterize the individual vortices in the Karman street. It does not yield good results in all cases, however. It is clear that there are values of the density

factor which yield optimum solutions; these values are not always equal to V_{∞}/\bar{V} , as the Prandtl-Tietjens theory would indicate. The best solutions appear to occur for values of density factor in the range of 0.8 to 1.4, depending on the test run. The analysis program in its current form cannot precisely determine the optimum value of density factor.

VII. Recommendations

Even though this thesis was itself a follow-on effort, there are several possible directions for future follow-on work to it.

1. Use a different optimization technique to find the c_1 , c_2 solution. The Newton-Raphson Method, while it is rapid when it does converge, is not reliable in all cases. In addition, the new method should incorporate constraints which prevent the method from iterating to a nonphysical solution, for example, with c_1 and/or c_2 negative.

2. Extend the study to include planar shock waves interacting with vortices by completing the design and fabrication of the slider valve.

3. Use an airfoil pulsed in the pitch mode to produce a single starting vortex and then subject the vortex to a shock wave.

4. Because density is an important parameter in vortex characterization, interferometry instead of schlieren techniques should be used. Since interferometry measures density directly, it is a more sensitive technique and can measure smaller changes in density than can schlieren techniques. Thus, tests can be made at lower Reynolds numbers,

and hence lower turbulence levels. The quantitative information available from the interferometer would also enable the actual density across the vortex to be plotted as a final check of the density variation across the vortices in the vortex street.

5. Incorporate a digital computer with the IFA-100 anemometer system so as to automate the acquisition of flow data. The most feasible means of doing this is to use the IFA-100 in conjunction with a transient recorder, which in turn stores and then sends the data to the computer. The microcomputer can then be used to store the data on diskette as well as perform the processing tasks.

6. Reformulate the method to take into account the variation of density across the vortex street. Since the density would no longer be constant, it is reasonable to assume that the point value rather than the average value of density is to be used in the convective mass flow calculation at each point in the vortex.

7. Using lower Reynolds number flows, investigate further the applicability of the Prandtl-Tietjens superposition concept to the technique of vortex characterization.

8. Verify that the vortices do indeed shed from the cylinder in a two-dimensional manner by taking schlieren photographs with the light path perpendicular to the cylinder axis. Verification can also be done with a three channel hot-film anemometer and correlation techniques.

Appendix A: Development of the Two-Vortex Assumption

Development of the Two-Vortex Assumption is composed of two smaller developments: derivation of more than one data point from a single anemometer trace and incorporation of the theoretical Equation (1) into the Two-Vortex Model.

Expansion of Data

As mentioned earlier, the anemometer provides a complete time history of the flow past the wire. As a vortex moves in space, its angle and radius to the anemometer change as its position changes.

Pictorally, we see that at two different times i_1 and i_2 for a vortex j , we have an $(r_j(i_1), \theta_j(i_1))$ and $(r_j(i_2), \theta_j(i_2))$ describing where the vortex is in relation to the anemometer (Figure 51).

Fig. 51. Temporal Expansion of Data

If the vortex is at time i_1 when the schlieren picture is taken, the $r_j(i_1)$ and $\theta_j(i_1)$ may be read from the picture. Also, noting vortex separation and frequency of passage gives the average convective velocity \bar{V} . If one considers a different time i_2 , and assumes the \bar{V} is constant and in the negative x-direction only, then one can mathematically move the vortex to any new location $r_j(i_2)$ and $\theta_j(i_2)$. Using simple geometry,

$$h = r_j(i_1)\sin\theta_j(i_1) = r_j(i_2)\cos\theta_j(i_2)$$

$$r_j(i_1)\cos\theta_j(i_1) = r_j(i_2)\cos\theta_j(i_2) - \bar{V}(i_2-i_1)$$

$$r_j(i_2) = \{[r_j(i_2)\cos\theta_j(i_2)]^2 + h^2\}^{1/2}$$

Therefore,

$$r_j(i_2) = \{[r_j(i_1)\cos\theta_j(i_1) + \bar{V}(i_2-i_1)]^2 + [r_j(i_1)\sin\theta_j(i_1)]^2\}^{1/2}$$

and

$$\theta_j(i_2) = \tan^{-1} \{ [r_j(i_1)\sin\theta_j(i_1)] / [r_j(i_1)\cos\theta_j(i_1) + \bar{V}(i_2-i_1)] \}$$

Note that the - sign in front of \bar{V} takes care of its negative direction and that, as drawn, $\cos\theta_j$ is negative. Thus, we have calculated a new (r,θ) position for the anemometer at a different time i_2 .

The anemometer data is obtained by moving a time increment $i_2 - i_1$ on the trace and reading the voltage at that point. The voltage value can then be applied to the calibration curve.

Development of the Two-Vortex Equations

The analysis begins with the elimination of time dependency from the vortex equation

$$pu = (c_1/r) (1 - \exp(-r^2/4\nu(t_0 + \Delta t))).$$

Considering the exponent term, one can make an order of magnitude estimate as to what t_0 should be (t_0 is defined as the time period which started when the vortex would have been an ideal $1/r$ type vortex and decayed to a more realistic free vortex form; Δt is on the order of .001 seconds, or the time the vortex is in the test section).

For a typical profile shown in Figure 2,

$$\nu(t_0 + \Delta t)/r_0^2 = 0.04$$

where ν = dynamic viscosity = 1.155×10^{-4} ft²/sec. Using $r_0 = 0.02604$ ft (cylinder diameter) we can rewrite the equation above as

$$t_0 + \Delta t = 0.04r_0^2/\nu$$

$$t_0 + \Delta t = 0.235 \text{ sec}$$

Since $\Delta t = 0.001$ sec, in the space of time the test takes place, $t_0 + \Delta t$ is essentially constant. Therefore, we can assume the vortices are time independent, and

$$\rho u = (c_1/r) (1 - \exp(-c_2 r^2))$$

Considering a generalized two-vortex system shown in Figure 52, one can write the total x-component of velocity at the anemometer as:

$$(\rho V)_x = (\rho u)_1 \sin \theta_1 + (\rho u)_2 \sin \theta_2 - (\overline{\rho V})$$

where

$$(\rho u)_1 = (-D_1 c_1 / r_1) (1 - \exp(-c_2 r_1^2))$$

$$(\rho u)_2 = (-D_2 c_1 / r_2) (1 - \exp(-c_2 r_2^2))$$

D_1, D_2 = direction of rotation; +1 counterclockwise,
-1 clockwise

c_1, c_2 = unknown coefficients

Fig. 52. Vortex Pair

Similarly, the total y-component is:

$$(\rho V)_y = (\rho u)_1 \cos \theta_1 + (\rho u)_2 \cos \theta_2$$

assuming that the convective transport is only in the negative x-direction.

The magnitude of the flow felt by the anemometer, then, is:

$$\begin{aligned} (\rho V) &= [(\rho V)_x^2 + (\rho V)_y^2]^{\frac{1}{2}} \\ &= \left\{ \left[\frac{-D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \sin \theta_1 \right. \right. \\ &\quad \left. \left. - \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \sin \theta_2 \right. \right. \\ &\quad \left. \left. - (\overline{\rho V}) \right]^2 + \left[\frac{-D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \cos \theta_1 \right. \right. \\ &\quad \left. \left. - \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \cos \theta_2 \right]^2 \right\}^{\frac{1}{2}} \end{aligned}$$

or, eliminating the -1 factor:

$$\begin{aligned} (\rho V) &= \left\{ \left[\frac{D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \sin \theta_1 \right. \right. \\ &\quad \left. \left. + \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \sin \theta_2 \right. \right. \\ &\quad \left. \left. + (\overline{\rho V}) \right]^2 + \left[\frac{D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \cos \theta_1 \right. \right. \\ &\quad \left. \left. + \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \cos \theta_2 \right]^2 \right\}^{\frac{1}{2}} \end{aligned}$$

Defining a function f as the difference between the right- and left-hand sides, we get

$$\begin{aligned}
 f = & \left\{ \left[\frac{D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \sin \theta_1 \right. \right. \\
 & + \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \sin \theta_2 \\
 & + (\overline{\rho V})^2 \left. \right] + \left[\frac{D_1 c_1}{r_1} (1 - \exp(-c_2 r_1^2)) \cos \theta_1 \right. \\
 & \left. \left. + \frac{D_2 c_1}{r_2} (1 - \exp(-c_2 r_2^2)) \cos \theta_2 \right]^2 \right\}^{\frac{1}{2}} - (\rho V)
 \end{aligned}$$

By multiplying out the terms, we get the form of Equation (11).

Under ideal conditions where all measurements are exact and there is no turbulence, for each data point, f would equal zero. But, there are errors associated with each data point, thus preventing an exact solution. Therefore, an error minimization is needed, wherein we try to obtain a "best fit" solution (c_1, c_2) which makes f as small as possible. A feasible way to do this is by taking many data points, each having its own f , and summing the squares of f :

$$z = - \sum_i f_i^2$$

where i represents each data point. Following the Newton-Raphson procedure in the Schaum's Outline: Operations Research (16:122) we can find the values of c_1 and c_2 which minimize the sum of the errors, squared. Using matrices, we define

$$\vec{c} = [c_1, c_2]^T$$

$$\vec{H}_f = [\partial^2 z / \partial c_i \partial c_j]_{i,j=1,2}^{i=1,2}$$

$$z = - \sum_{i=1}^N f_i^2 \quad (N = \text{number of data points})$$

Therefore,

$$\vec{c}_{\text{NEW}} = \vec{c}_{\text{OLD}} + (\vec{H}_f)^{-1} |_{\text{OLD}} (\partial z / \partial c_1, \partial z / \partial c_2)$$

defines a recursive relationship (16:112) which permits an iterative type solution. One then iterates until successive z values are within an acceptable error limit ϵ :

$$|z_{\text{NEW}} - z_{\text{OLD}}| / z_{\text{OLD}} < \epsilon$$

This is best done using a computer since it requires lengthy calculations. The derivations of the first and second partial derivatives of z with respect to c_1 and c_2 are long and algebraically involved, but are not difficult and will not be repeated here.

The BASIC computer program "DATANAL8" used to perform the Newton-Raphson routine is shown below. The program begins by asking for the run number and if the raw data is stored on disk. If the data is on disk, the program asks for the filename (in MMDDRR format; M=month, D=day, R=run) and then retrieves the file and begins processing. If the data is not on disk, then the program asks for the information. After obtaining the raw data, the program requests initial starting points for c_1 and c_2 . After the starting points are inputted, the program computes the first and second partial derivatives of the function z with respect to c_1 and c_2 and, through the Newton-Raphson algorithm computes new values for c_1 and c_2 . If the error terms z for the old and new (c_1, c_2) pair are within 1 percent of each other, the program terminates execution; if the errors are different by more than 1 percent, then the program conducts another iteration.

Appendix B: Data Display Program "DISP4"

The following program accepts a c_1 and c_2 pair as well as the quantitative data for a particular run and generates a theoretical Karman vortex street to compare to the experimental Karman vortex street over several cycles. It uses the same basic ideas on expansion of data as "DATANAL8." The program is written in BASIC and outputs the theoretical and experimental street data to an output file, on diskette, as directed by the user. The data can then be plotted for a direct comparison between theory and experiment.

Appendix D: Schlieren and Anemometer Measurements

Although a great many test runs were made, only those with clear street definition were analyzed. Table II and Figures 53 through 58 summarize the data from those runs. Included are the c_1, c_2 and density factor values derived from the data analysis. It should be noted that the zero trace level on the anemometer trace is actually 2 volts due to the offset feature of the IFA-100. The voltage levels were converted to flow levels via the calibration equation:

$$\rho u (\text{lbm/ft}^2 \text{ sec}) = -887.65 + 2237.05E - 1927.52E^2 \\ + 694.10E^3 - 87.57E^4$$

where E is the anemometer output in volts.

In Table II, those entries with a * by them indicate that the density factor was equal to:

$$fd = V_{\infty} / \bar{V}$$

so as to use the Prandtl-Tietjens superposition theory in the analysis program.

VITA

First Lieutenant John B. Wissler was born on 7 January 1958 in Bremerton, Washington. He graduated from Radford High School in Honolulu, Hawaii in 1976 and went to the U.S. Naval Academy (1976-1978), George Washington University (1978-1980), and the University of Maryland (1980-1981) where he received a degree of Bachelor of Science in Mechanical Engineering in December, 1981. Upon graduation, he attended Air Force Officer Training School, receiving his commission in the USAF in April, 1982. He then served as an R&D Munitions Test Engineer with the 3246th Test Wing, Eglin AFB, Florida, until entering the School of Engineering, Air Force Institute of Technology, in May, 1984.

→ This investigation involved taking schlieren and hot-film anemometer data on Karman vortex streets, then developing a means of characterizing the individual vortices in a street using a schlieren picture and the corresponding anemometer trace. A ThermoSystems, Inc. IFA-100 anemometer system, with a Tektronix 425 oscilloscope, was used to record an anemometer trace. The trace was captured on photographic film. The oscilloscope also fired a Cordin Model 5401 spark lamp, which provided, via a schlieren optical system, a physical picture of the Karman streets formed behind a 5/16-inch dia cylinder in a 2-inch by 2-inch square cross-section test region with a Mach 0.43 flow. Distance and angle information were obtained from the schlieren photographs, and timing and anemometer output voltage were obtained from the anemometer trace photograph using an HP-9874A digitizer. The data were analyzed using a Newton-Raphson method to solve for two constants, c_1 and c_2 , which should have completely characterized the vortices in the vortex street, assuming the vortices followed the theoretical equation for a combined free and forced vortex. It was assumed that the superposition of two vortices plus the mean flow were the parameters influencing the flow at any point in space and time. The core supremacy principle, which says that in a vortex core only one vortex contributes to the flow, was used in the data analysis. It was found that generally close fits between the theoretical data using the solved for constants c_1 and c_2 , and the experimental data from the anemometer were possible, thus indicating reasonable vortex characterization.
